call to _read. The reason is that in certain\n  // synthetic stream cases, such as passthrough streams, _read\n  // may
be a completely synchronous operation which may change\n  // the state of the read buffer, providing enough data
when\n  // before there was *not* enough.\n  //\n  // So, the steps are:\n  // 1. Figure out what the state of things will
be after we do\n  // a read from the buffer.\n  //\n  // 2. If that resulting state will trigger a _read, then call _read.\n  //
Note that this may be asynchronous, or synchronous. Yes, it is\n  // deeply ugly to write APIs this way, but that still
doesn't mean\n  // that the Readable class should behave improperly, as streams are\n  // designed to be sync/async
agnostic.\n  // Take note if the
_read call is sync or async (ie, if the read call\n  // has returned yet), so that we know whether or not it's safe to
emit\n  // 'readable' etc.\n  //\n  // 3. Actually pull the requested chunks out of the buffer and return.\n  // if we need a

for it, since that implies a thing where\n// some bits pass through, and others are simply ignored. (That would\n// be
a valid example of a transform, of course.)\n/\n// While the output is causally related to the input, it's not a\n//
necessarily symmetric or synchronous transformation. For example,\n// a zlib stream might take multiple plain-text
writes(), and then\n// emit a single compressed chunk some time in the future.\n/\n// Here's how this works:\n/\n//
The Transform stream has all the aspects of the readable and writable\n// stream classes. When you write(chunk),
that calls _write(chunk,cb)\n// internally, and returns false if there's a lot of pending writes\n// buffered up.
When you call read(), that calls _read(n) until\n// there's enough pending readable data buffered up.\n/\n// In a transform
stream, the written data is placed in a buffer. When\n//
_read(n) is called, it transforms the queued up data, calling the\n// buffered _write cb's as it consumes chunks. If
consuming a single\n// written chunk would result in multiple output chunks, then the first\n// outputted bit calls the
readcb, and subsequent chunks just go into\n// the read buffer, and will cause it to emit 'readable' if necessary.\n/\n//
This way, back-pressure is actually determined by the reading side,\n// since _read has to be called to start

```

processing a new chunk. However, a pathological inflate type of transform can cause excessive buffering here. For example, imagine a stream where every byte of input is interpreted as an integer from 0-255, and then results in that many bytes of output. Writing the 4 bytes {ff,ff,ff,ff} would result in 1kb of data being output. In this case, you could write a very small amount of input, and end up with a very large amount of output. In such a pathological inflating mechanism, there'd be no

way to tell the system to stop doing the transform. A single 4MB write could cause the system to run out of memory. However, even in such a pathological case, only a single written chunk would be consumed, and then the rest would wait (un-transformed) until the results of the previous transformed chunk were

```
